

# Malignant transformation in oral lichen planus and lichenoid lesions: a 14-year longitudinal retrospective cohort study of 829 patients in New Zealand

Guangzhao Guan, BDS, MBChB, DclinDent,<sup>a</sup> Li Mei, BDS, DDS, PhD,<sup>b</sup> Ajith Polonowita, BDS, MDS,<sup>a</sup> Haizal Hussaini, BDS, MDentSci, PhD,<sup>a</sup> Benedict Seo, BDS, DclinDent, PhD,<sup>a</sup> and Alison Mary Rich, BDS, MDS, PhD<sup>a</sup>

**Objective.** The aim of this study was to identify the rate of malignant transformation in a longitudinal cohort of patients with oral lichen planus and oral lichenoid lesion (OLP/OLL) and to assess the associations between clinicopathologic aspects and malignant transformation.

**Study Design.** Data were taken from the records of 829 patients histologically diagnosed with OLP/OLL in the years 2005 to 2018.

**Results.** Of the study patients, 548 (66.1%) were females and 281 (33.9%) were males. The average age at diagnosis was 57.3 years. The hyperplastic type was the most frequent (58.5%). Most patients had multiple sites of involvement, with the buccal mucosa being the most frequent site of biopsy. Oral epithelial dysplasia developed in 5 (0.6%) patients with a previous histologic diagnosis of OLP/OLL and developed oral squamous cell carcinoma (OSCC) in 23 patients (2.8%) during the follow-up period. The atrophic/ulcerative forms are 25.8 times more likely to progress to OSCC compared with the hyperplastic types (hazard ratio [HR] 25.8;  $P < .05$ ). The HR increases by 5% with every year of age (HR 1.05; 95% confidence interval;  $P < .05$ ).

**Conclusions.** In our study, oral epithelial dysplasia developed in less than 1% of patients with OLP/OLL, and OSCC in 2.8% during the follow-up period. The atrophic/ulcerative forms are 25.8 times more likely to progress to OSCC compared with the hyperplastic types. The HR increases by 5% with every year of age. (Oral Surg Oral Med Oral Pathol Oral Radiol 2020;130:411–418)

The association between oral lichen planus (OLP) and oral cancer has been debated for decades. The World Health Organization (WHO) defined OLP as a potentially malignant disorder, associated with a small increased risk of oral cancer.<sup>1</sup> Recent systematic reviews have suggested that the erosive type, female gender, and tongue site are risk factors for malignant transformation.<sup>2,3</sup> The modified 2003 WHO diagnostic criteria suggested that oral epithelial dysplasia should not be present for a diagnosis of OLP, in an attempt to reduce the controversy relating to the so-called oral lichenoid dysplasia (OLD), a term proposed by Krutchkoff and Eisenberg in 1985 to describe lesions with the histologic features of both OLP and oral epithelial dysplasia.<sup>4–6</sup> Lichenoid dysplasia has a significantly higher risk of malignant transformation compared with OLP/oral lichenoid lesion (OLL).<sup>4,7</sup> The rate of malignant transformation varies from 0% to 5% in both retrospective and prospective cohort studies.<sup>8–10</sup> However, when lichenoid dysplasia is excluded, the malignant transformation rate can be as low as 0.9%.<sup>7,11</sup> The term *OLL* and the diagnosis have been discussed for many years.<sup>12,13</sup> The exact etiology of OLL remains unknown. OLL may present as a

unilateral lesion, rather than bilateral lesions, which can usually be seen in OLP.<sup>13</sup> OLL may be associated with the use of several dental materials and medications, such as antihypertensives, nonsteroidal anti-inflammatory drugs, anticonvulsants, and antimalarials.<sup>14</sup> The histopathologic features of OLL are similar to those of OLP. However, some studies have suggested that OLL may have a higher number of apoptotic keratinocytes, more diffused mixture of plasma and eosinophil cells, and deeper inflammatory infiltration compared with OLP.<sup>13,15</sup>

There are no reports on the incidence rate of malignant transformation in OLP/OLL in a New Zealand population. The aim of this study was to identify the rate of malignant transformation in a retrospective study of a cohort of patients histologically diagnosed with OLP/OLL to assess the associations between malignant transformation and clinicopathologic characteristics.

## MATERIAL AND METHODS

The study was approved by the Human Research Ethics Committee, University of Otago, Dunedin, New Zealand (HD 18/075). This retrospective study included all patients with histopathologic a diagnosis of OLP or

## Statement of Clinical Relevance

Atrophic/ulcerative oral lichen planus is 25.8 times more likely to progress to oral cancer compared with the hyperplastic forms. The expected hazard ratio increases by 5% with every year of age.

OLL, provided by registered oral pathologists at the Oral Pathology Centre, University of Otago (Dunedin, New Zealand), in the years 2005 to 2018. Data collected from the biopsy request forms included gender, age at the time of the initial biopsy, clinical characteristics of the lesion (appearance and sites of oral involvement), and histologic diagnosis. This information was anonymized and recorded on an Excel spreadsheet. Patients who did not fulfill the clinical and histologic criteria for OLP and OLL were excluded from the analysis.

The diagnosis was made as OLP and related lesions, according to the modified 2003 WHO criteria.<sup>4,16,17</sup> According to these criteria, the histologic features to note are the presence of a well-defined, band-like zone of inflammatory cells in the superficial connective tissue; signs of liquefaction degeneration in the basal cell layer; and absence of oral epithelial dysplasia. For the present study, any case with histologically identified features of OLP but also no dysplasia (the so-called OLD) was excluded. In addition, the oral pathologists referred to patient notes and clinical photographs and, if necessary, discussed the case with the clinician to confirm various clinical features before a histologic diagnosis was made. Nevertheless, the diagnostic laboratory reported the diagnosis as one entity, OLP or OLL, with the expectation that the clinician would be responsible for excluding a lichenoid reaction. Clinically, reticular, papular, and plaque-like lesions were considered to be the hyperplastic type, and the atrophic, erosive, ulcerative, or bullous lesions were considered to be the atrophic/ulcerative type.<sup>7,9,18,19</sup> For a clinical diagnosis of OLP, the following criteria had to be met:

1. Presence of bilateral, more or less symmetric lesions
2. Presence of a lace-like network of slightly raised white lines (reticular pattern)
3. Erosive, atrophic, bulbous, and plaque-type lesions, which were only accepted as a subtype in the presence of reticular lesions elsewhere in the oral mucosa

For the purpose of this study, OLP, OLL, or oral lichenoid reaction were considered to be one entity and included the following scenarios:

1. Clinically typical of OLP but histopathologically only compatible with OLP
2. Histopathologically typical of OLP but clinically only compatible with OLP
3. Clinically compatible with OLP and histopathologically compatible with OLP<sup>4</sup>
4. All lesions with initial biopsy showing OLP/OLL and concurrent epithelial dysplasia (i.e., OLD excluded).

After this baseline sample was collected, the medical and dental records, available at the Faculty of Dentistry, University of Otago, of every patient diagnosed with OLP or OLL between 2005 and 2018 were checked prospectively to determine whether or not they were subsequently diagnosed with oral squamous cell carcinoma (OSCC) or oral epithelial dysplasia. Furthermore, as an additional check, all cases of OSCC or oral epithelial dysplasia diagnosed in the Oral Pathology Centre at the University of Otago between 2005 and 2018 were checked to see whether or not there was a previous diagnosis of OLP or OLL.

Statistical analysis of the data was performed by using Stata/IC version 15.0 (StataCorp, College Station, TX). Continuous variables were expressed as mean  $\pm$  standard deviation (SD) if normally distributed or as median and quartiles if they had a skewed distribution. Categorical variables were described as counts and percentages. The Cox proportional hazard regression model was used to estimate hazard ratio (HR), and a multivariable model was used to adjust the potential confounders, including patient age and gender and lesion location and clinical appearance. A *P* value of less than 0.05 was considered to indicate statistical significance.

## RESULTS

Data from a total of 829 patients with OLP/OLL were analyzed retrospectively; 548 (66.1%) were females, and 281 (33.9%) were males, giving a female-to-male ratio 2.0:1 (Figure 1). The youngest patient was 9 years old, and the oldest was 90 years old. The average age at diagnosis of OLP/OLL was 57.3 years. The mean age at diagnosis was 55.1 years for males and 58.5 years for females. The hyperplastic type of OLP/OLL was observed in 485 patients (58.5%), of which 184 were males and 301 were females. The mean age at diagnosis of the hyperplastic type was 54.2 years and 57.1 years for males and females, respectively (Table I). The atrophic/ulcerative forms of OLP were diagnosed in 344 patients (41.5%), including 97 males and 247 females. The mean age at diagnosis of the atrophic/ulcerative form was 56.7 years and 60 years for males and females, respectively. Most patients had multiple oral lesions. The buccal mucosa was the most common site of biopsy (56.3%), followed by the gingivae (18.8%) and the tongue (18.7%). Biopsy of lesions on the floor of the mouth and on the soft palate was uncommon (Figure 2).

Of the 829 patients, 5 patients (0.6%) previously diagnosed histologically with OLP/OLL developed an oral mucosal dysplastic lesion, and 23 patients (2.8%) developed OSCC during the follow-up period (Table II). None of the 23 patients reported smoking and heavy alcohol consumption. The mean duration of

Fig. 1. Age and gender of 829 patients with oral lichenoid lesion (OLL)/oral lichen planus (OLP).

malignant transformation after the first biopsy was  $4.3 \pm 2.2$  years. The mean duration of oral mucosal dysplasia transformation was  $5.8 \pm 2.5$  years. A Cox proportional hazards model was used to estimate the HR and 95% confidence interval (CI) for malignant transformation among patients with OLP/OLL (Table III). The Cox proportional hazards model showed a 5.2-fold increase in hazard (malignant transformation) in females compared with males, and it was statistically significant (HR 5.2; 95% CI 1.2–22.3). However, after being adjusted for different sites of biopsy, clinical appearance of the lesion, and patient age, no statistical significance was found. The atrophic/ulcerative forms were 32.2 times more likely to progress to OSCC compared with the hyperplastic types (HR 32.2; 95% CI

4.3–239.3;  $P < .05$ ). After adjustment for patient gender and age and lesion location, the association of malignant transformation with the atrophic/ulcerative forms was still statistically significant (HR 25.8; 95% CI 3.4–191.8;  $P < .01$ ). The HR increased by 5% with every year of age (HR 1.05; 95% CI 1.01–1.09;  $P < .01$ ), and it was statistically significant. Although the floor of the mouth and the tongue had HRs of 2.8 and 1.3, respectively, they were not statistically significant in both the adjusted and unadjusted models.

### DISCUSSION

This study analyzed patients with OLP/OLL and the association with malignant transformation. Our study had several limitations. First, we did not separate OLP

Table I. Clinical characteristics of OLP/OLL lesions

	Current/ ex-smoker N (%)	Alcohol consumption N (%)	Hepatitis C infection N (%)	Age at the OLP/OLL diagnosis (Mean $\pm$ SD)	Types of OLP/OLL N (%)

\*P < .05 considered significant.

OLP lesions gain dysplastic features. Third, some of our patients' medical records had insufficient details. Finally, our results were dependent on the site of biopsy, and we did not tabulate patients with concurrent multiple sites of involvement. However, this is the first study to show that there was a 5% increase in the expected hazard relating to a 1-year increase in age (i. e., the expected hazard was 0.05 times higher in a patient who was 1 year older than another), holding patient gender and the lesion location and clinical appearance constant. The atrophic/ulcerative forms were 25.8 times more likely to progress to OSCC compared with the hyperplastic forms. These results imply that the atrophic/ulcerative forms OLP/OLL should be managed more aggressively because a cumulative effect could significantly increase the rate of malignant transformation year over year. In general, the results of the present New Zealand study were compatible with those of previous studies (Table IV). Although it is clearly reported in the international literature that OLP/OLL does occur in all age groups, our study confirmed that in New Zealand, middle-aged females were most commonly affected.<sup>18,20,21</sup> The age at diagnosis of OLP/OLL was usually between 50 and 70 years, with an incidence peak in both males and females in the age group 51 to 60 years. In agreement with other similar studies, the majority of our patients with OLP/OLL were females (F:M ratio = 2:1), with an average age of 57 years at the time of diagnosis. Only 1 child and 3 teenagers were present in this study, perhaps reflecting the rarity of OLP/OLL in individuals younger than 20 years of age.<sup>22-24</sup>

As expected clinically, a mixture of white and red lesions with a bilateral symmetric pattern were seen in these patients. The hyperplastic type, with a reticular pattern, white papules, and plaque-like (white) lesions, represented more than half the patients (58.5%). This proportion of patients was less compared with that reported in a previous series; in Chinese,<sup>25</sup> Swedish,<sup>26</sup> Italian,<sup>19</sup> and American<sup>27</sup> studies, the atrophic/ulcerative forms were more predominant.

One of the most important issues concerning OLP/OLL is its potential for malignant transformation. Although the WHO has categorized OLP as a potentially malignant disorder, the risk of malignant transformation has been a subject of debate.<sup>6</sup> The overall

malignant transformation rate is estimated to be 0% to 5%, with the highest rate noted with the atrophic/ulcerative forms (see Table III). Although there are no known histopathologic predictive factors of malignant transformation of OLP, the clinical presence of the atrophic/ulcerative forms is known to indicate a greater predisposition to cancer development.<sup>2,28</sup> It has been suggested that the atrophic/ulcerative forms predispose the oral mucosa to damage from carcinogenic agents, such as alcohol and tobacco, and/or to infections, such as with *Candida albicans*.<sup>28</sup> However, not all patients in whom cancer developed were tobacco smokers or drank alcohol daily, suggesting that malignant transformation may be part of the natural evolution of OLP or is related to other unknown factors. We found that malignant transformation was uncommon but still a significant risk. Of the patients in our study, OSCC developed in 23 (2.8%), as reported by other studies as well.<sup>9,10,18-21,25,27,29-48</sup>

In our study, we confirmed the findings of other studies which demonstrated that the atrophic/ulcerative forms had a higher malignant transformation rate compared with the hyperplastic forms.<sup>25-28,47,49</sup> It has been suggested that chronic inflammation might play an important role in the progression of OLP/OLL lesions to OSCC.<sup>50</sup> Current research has suggested that cytokines released as part of chronic inflammatory processes might participate in malignant transformation.<sup>51-53</sup> Cytokines, such as interleukin-6 (IL-6), IL-17, and IL-23 have been shown to contribute to tumor progression, and tumor necrosis factor (TNF)- $\alpha$ / $\beta$  and IL-6 promote cancer cells to grow and survive.<sup>54</sup> Multiple cells that expressed IL-17 were found in both OLP and OSCC, indicating that IL-17 might play a role in the pathogenesis of OSCC.<sup>55,56</sup> In addition, elevated levels of salivary TNF- $\alpha$ , IL-6, and IL-10 were found in the saliva of patients with OLP/OLL with high-grade dysplasia and OSCC.<sup>51,57-60</sup> Long-standing chronic inflammation is associated with increased risk of malignant transformation in some conditions, such as inflammatory bowel diseases.<sup>61</sup> Chronic inflammation induces constant healing and repair, thereby improving cellular survival, and is associated with the release of numerous cytokines and other molecules into the local environment.<sup>62</sup> Potentially, genetic predisposition of basal keratinocytes, in

conjunction with ongoing chronic inflammation, might lead to the initiation of carcinogenesis.

## CONCLUSIONS

The present study has provided information about the epidemiologic and clinical characteristics of patients with OLP/OLL in New Zealand and about the rate of malignant transformation in this cohort. The atrophic/ulcerative clinical forms were more likely to progress to OSCC compared with the hyperplastic types. The malignant transformation rate in the present study was 2.8%, with a 5% increase in the HR with every year of age. The mechanisms that are related to malignant transformation in OLP are still unclear but are likely linked to persistent chronic inflammation. It is important that patients with OLP/OLL, especially those with the atrophic/ulcerative type, be monitored through their entire life by clinicians so that any concerning clinical changes can be observed and investigated as early as possible.
